ABSTRACT

Background Microorganisms that can be used for their lytic activity against tumor cells as well as inducing or reactivating antitumor immune responses are a relevant part of the available immunotherapy strategies. Viruses, bacteria and even protozoa have been largely explored with success as effective human antitumor agents. To date, only one oncolytic virus—T-VEC—has been approved by the US Food and Drug Administration for use in biological cancer therapy in clinical trials. The goal of our study is to evaluate the potential of a livestock pathogen, the protozoan *Neospora caninum,* non-pathogenic in humans, as an effective and safe antitumorous agent.

Methods/Results We demonstrated that the treatment of murine thymoma EG7 by subcutaneous injection of *N. caninum* tachyzoites either in or remotely from the tumor strongly inhibits tumor development, and often causes their complete eradication. Analysis of immune responses showed that *N. caninum* had the ability to 1) lyze infected cancer cells, 2) reactivate the immunosuppressed immune cells and 3) activate the systemic immune system by generating a protective antitumor response dependent on natural killer cells, CD8-T cells and associated with a strong interferon (IFN)-γ secretion in the tumor microenvironment. Most importantly, we observed a total clearance of the injected agent in the treated animals: *N. caninum* exhibited strong anticancer effects without persisting in the organism of treated mice. We also established in vitro and an in vivo non-obese diabetic/ severe combined immunodeficiency mouse model that *N. caninum* infected and induced a strong regression of human Merkel cell carcinoma. Finally, we engineered a *N. caninum* strain to secrete human interleukin (IL)-15, associated with the alpha-subunit of the IL-15 receptor thus strengthening the immuno-stimulatory properties of *N. caninum*. Indeed, this NC1-IL15hRec strain induced both proliferation of and IFN-γ secretion by human peripheral blood mononuclear cells, as well as improved efficacy in vivo in the EG7 tumor model.

Conclusion These results highlight *N. caninum* as a potential, extremely effective and non-toxic anticancer agent, capable of being engineered to either express at its surface or to secrete biodrugs. Our work has identified the broad clinical possibilities of using *N. caninum* as an oncolytic protozoan in human medicine.

BACKGROUND

As of 2011 immunotherapy, which educates the immune system to effectively fight cancer cells, has been added to the arsenal of conventional cancer therapies. Several avenues have been explored such as immune checkpoint blockade[1] and CAR-T[2 3] therapies and, for a minority of specific cases, significant improvement in survival outcomes have resulted. Live microorganisms also represent a promising therapeutic approach due to their lytic activity on tumor cells and/or their ability to stimulate the immune system, especially via target molecules of innate immunity. Attenuated viruses and bacteria have been largely explored as vaccine vectors to elicit T-cell-mediated immunity and to induce protective response against tumor development.[4–6] Moreover, those microorganisms can be genetically modified to further express molecules that potentiate immune responses and/or target tumor antigens. Thus, the approval of the first virotherapy was based on the use of a herpes simplex virus (HSV) expressing granulocyte-macrophage colony-stimulating factor (GM-CSF) and genetically modified to preferentially target tumor cells for the treatment of metastatic melanomas has attracted tremendous attention in the *field of cancer* therapy.[7] More recently, therapeutic approaches using live, tumor-targeting bacteria (*Salmonella, Listeria, Clostridium, Bifidobacterium* and so on) have emerged as promising cancer treatment strategies.[8] Also used as vectors for delivering or expressing tumor suppressor genes or tumor-associated antigens, bacteria have showed promising

antitumor activity in various preclinical tumor models.[9] Among other microorganisms, intracellular protozoa have been identified as a new avenue of exploration. In 2011, Junqueira *et al* demonstrated that *Trypanosoma cruzi* was highly efficient in inducing T-cell-mediated immunity and protection against melanoma.[10] The immunostimulatory properties of *Toxoplasma gondii* have also been known for many years. Indeed, chronic infection and even parasite extracts have conferred resistance and cross protection in the mouse to many pathogens including viruses,[11] bacteria,[12] parasites,[13] yeast[14] and even mammary tumors.[15] Recently, new studies have confirmed the interest of using *T. gondii* in antitumor immunotherapy. Those studies used live, non-replicating *Toxoplasma*, named CPS (for disruption of the Carbamoyl Phosphate Synthetase gene).[16] Tumor regressions were observed in the case of murine melanoma (B16F10), ovarian cancer (ID8) and pancreatic cancer (Pan02) following intratumorous injections of CPS.[17–19] In any case, the living protozoan, by activating the innate immune system, reverses the immunosuppression and leads to the reactivation of a specific immune response against the tumor.

However, those pathogens can persist for a long time in human bodies and in some cases, if not treated, can induce severe diseases. Thus, it seems appropriate to determine if the use of a naturally occurring protozoan, non-infectious for humans, can be a relevant therapeutic agent. To explore this opportunity, we focused on the livestock pathogen *Neospora caninum,* an intracellular protozoa closely related to *T. gondii*, identified in 1984 by Bjerkås *et al*.[20] Little is known about the epidemiology of *N. caninum* infection in humans. While the few available sero-epidemiological studies demonstrated very low sero-positivity rates in *T. gondii*-seropositive individuals,[21] blood donors,[22] HIV-infected patients or patients with neurological disorders,[23] *N. caninum* has not been demonstrated in human tissues and there is no evidence that neosporosis is a zoonosis.

As in humans, very low frequency of seropositivity with *N. caninum* was detected in the *Mus domesticus* population (3%).[24] However, several mouse models have been developed as an attempt to study *N. caninum* infection suggesting that a non-natural host can be infected by the protozoa. Furthermore, those data raise the question if *N. caninum* has infectious potential for human cells even if humans are resistant to the disease—which could thus be a safe microbial anticancer therapy.

We here report that treatment of EG7 thymoma in syngeneic mice by live *N. caninum* administered by remote (subcutaneous) or local (intratumor) injection can successfully inhibit both early and established tumor development. However, killed microbes were unable to mediate regression of tumors suggesting that the infectious nature of *N. caninum* was a required feature for successful protection.

The analysis of the immune responses and interactions between *N. caninum* and tumor cells allowed us to highlight that *Neospora* has the capacity to 1) directly destroy the cancer cells that it infects, 2) reactivate the local suppressed immune cells at the site of the tumor, 3) activate the systemic immune system by promoting the recruitment of immune cells to the site of the tumor leading to the establishment of a long-term antitumor response and, finally, 4) be reduced to undetectable levels suggesting the absence of persistence of *N. caninum* in tissues. We believe that our data merit further studies to support the possible application of *N. caninum* as a new, valuable immunotherapeutic agent for human cancer, a belief further reinforced by results obtained with human Merkel cell carcinoma and with engineered *Neospora* to express the human complex of interleukin (IL)-15 and the *Sushi domain* of *IL-15 receptor α* chain to improve effector response.

MATERIALS AND METHODS
Mice
Female C57BL/6 and non-obese diabetic/severe combined immunodeficiency (NOD/SCID) mice aged 8 weeks were purchased from CER Janvier (Le Genest Saint Isle, France) and maintained under pathogen-free conditions in the animal facility of the University of Tours.

Parasites
N. caninum (NC1 strain) and *T. gondii* (RH strain) tachyzoites were grown as described previously.[25] For mouse injections, tachyzoites were collected by centrifugation at 600 g for 10 min and washed in phosphate-buffered saline (PBS). Heat-killed tachyzoites were obtained by heating freshly isolated tachyzoites 30 min at 60°C.

The *N. caninum* total antigenic extract (TE) was prepared following the protocol described for *T. gondii* antigenic extract.[26]

Tumor cell
The murine thymoma cell line EG7 (EL4-OVA: EL-4 thymoma cells transfected with chicken albumin cDNA) was obtained from ATCC (CRL-2113). Tumor cells were cultured in RPMI (Pan Biotech) with 10% of fetal calf serum (FCS) (Dutscher), 0.05 mM of 2-mercaptoethanol (Pan Biotech), 50 IU/mL of penicillin/streptomycin (Pan Biotech) and 0.4 mg/mL geneticin (G418, Pan Biotech). The WaGa (RRID:CVCL_E998) cell line was used for Merkel cell carcinoma (MCC) studies, and was cultured in RPMI containing 10% FCS, 100 U/mL penicillin, streptomycin and amphotericin B.

Experimental procedures and sample collection
EG7 ($5×10^5$) or WaGa (10^7), associated with 10% Matrigel (10 mg/mL, Corning) cells were subcutaneously inoculated in the flank of mice. Mice were then injected intratumorally or subcutaneously in the opposite flank with isolated tachyzoites in PBS, at the doses and times indicated in the figures.

Tumor volume was determined as $\varpi/6 \times width \times length \times height$. Blood sera were collected via cheek bleeds from animals at the indicated time points.

Spleens and lymph nodes were mechanically disrupted, to obtain cell suspensions. The cells were then either plated in RPMI (5% FCS, 2% Hepes, 1% glutamine, 1% sodium-pyruvate, 50 mL/mL β-mercapto-ethanol, 100 U/mL penicillin and streptomycin) for in vitro restimulation or resuspended in PBS–1% BSA–0.2mM EDTA for flow cytometry analysis.

Tumors were harvested, weighed and measured after dissection. A first sample was collected and stored at −80°C for further quantitative PCR (qPCR) analysis. Other samples were collected respectively in 4% formol or 4% paraformaldehyde for histological analysis and immunofluorescence on frozen section, respectively. The rest of the tumor was dissociated using the Tumor Dissociation Kit, mouse (Miltenyi Biotech) and gentleMACS Dissociator (Miltenyi Biotech). Cells were resuspended (PBS, 2mM EDTA, 1% fetal bovine serum) for staining and flow cytometry analysis.

Cell depletion
Ultra-LEAF purified antimouse CD4 (GK1.5), antimouse CD8 (53–6.7), antimouse NK1.1 (PK136), antimouse Ly-6G (1A8) from BioLegend and clodronate liposomes from Liposoma were used for cells depletion. Ultra-LEAF purified Rat IgG2a, Rat IgG2b, mouse IgG2a isotype control antibodies from BioLegend, control liposomes from Liposoma and PBS were used like controls. Antibody (30 μg), liposomes (50 μL) or PBS were injected intratumorally 1 day after *N. caninum* treatment and then every 2–3 days until the sacrifice of mice.

Cellular analysis and flow cytometry
Antibody reagents were obtained from Miltenyi Biotech: REA clones of antimouse CD3-APC-Vio770 (REA606), CD4-Vioblue (REA 604), CD8a-PE-Vio770 (REA 601), Foxp3-Vio515 (REA 788), NKp46-APC (REA 815), CD11c-PE (REA 754), CD11b-APC-Vio770 (REA 592), Ly6C-Vioblue (REA 796), Ly6G-PE-Vio770 (REA 526). Foxp3 staining was performed using Foxp3 Staining Buffer Set (Miltenyi Biotech).

Flow cytometry analysis was performed using a Miltenyi 8-color MACSQuant, and data were analyzed using Flowlogic (Miltenyi Biotech).

Cytokine detection
Cytokine production in splenocyte culture supernatants and/or tumor dissociation supernatants were evaluated by ELISA with specific kits: IL-1β, IL-6, IL-12p40, IL-18 and transforming growth factor (TGF)-β (eBioscience), CCL2 and VEGF (Invitrogen), IL-15 and PDL1 (R&D systems). For GM-CSF, interferon (IFN)-γ, IL-2, IL-4, IL-5, IL-10, IL-12p70, IL-17A, IL-23 and tumor necrosis factor (TNF)-α, MACSPlex cytokine 10 kit (Miltenyi Biotec) was used according to the manufacturer's instructions.

Statistical analysis
All experiments were repeated at least two times with similar results between experiments. Statistical analysis was performed using GraphPad Prism software. P values <0.05 were considered to be statistically significant. Error bars show the SEM. Bar graphs were analyzed by one-way analysis of variance and scatter plots of tumor volume and weight were compared using Kruskal-Wallis nonparametric test.

More method details are provided in the online supplementary material and methods file.

RESULTS
N. caninum live tachyzoites induce the production of proinflammatory cytokines by mouse and human immune cells
Since humans are not natural hosts of *N. caninum* and the cross-talk between the protozoa and human innate immune cells has not yet been shown, it is important to study in vitro the relationship between *Neospora* and such cells in terms of infection and activation. Furthermore, those interactions should be also evaluated on mouse cells as a prerequisite to anticancer immunotherapy assay in mouse model.

We first studied the invasion and survival capacity of *N. caninum* tachyzoites in mouse bone marrow dendritic cells (BMDCs) and human blood dendritic cells (DCs), and their respective induced cytokine expression patterns.

We observed that *N. caninum* tachyzoites had entered, survived and multiplied within human DCs demonstrating for the first time that a strictly non-zoonotic protozoan could infect and proliferate in human DCs (figure 1A). We also demonstrated that human DCs secreted proinflammatory cytokines such as IL-12, TNF-α, IL-10 and IL-6 in response to stimulation with live *N. caninum* tachyzoites (figure 1B). Similar infectious capacity and cytokine induction profiles were observed in mouse cells including BMDCs (figure 1C,D), and in mouse macrophages and neutrophils (online supplemental figure 1). However, in contrast to mouse BMDCs, human DCs failed to secrete those important innate cytokines when exposed to dead protozoa. Finally, soluble tachyzoite antigens were not able to activate murine or human DCs.

In context of immunotherapeutic treatment with *N. caninum*, those findings convincingly suggest that the use of live parasites is a *sine qua non* condition for inducing robust immune responses.

Selection of the most immunogenic dose of *N. caninum* tachyzoites for immunotherapy assay in mice
To determine if *N. caninum* can induce a strong and early immune response without toxicity, mice were subcutaneously inoculated with several doses of *N. caninum* tachyzoites (2×10^3 to 2×10^7 per mouse). Significant humoral and cellular immune responses were
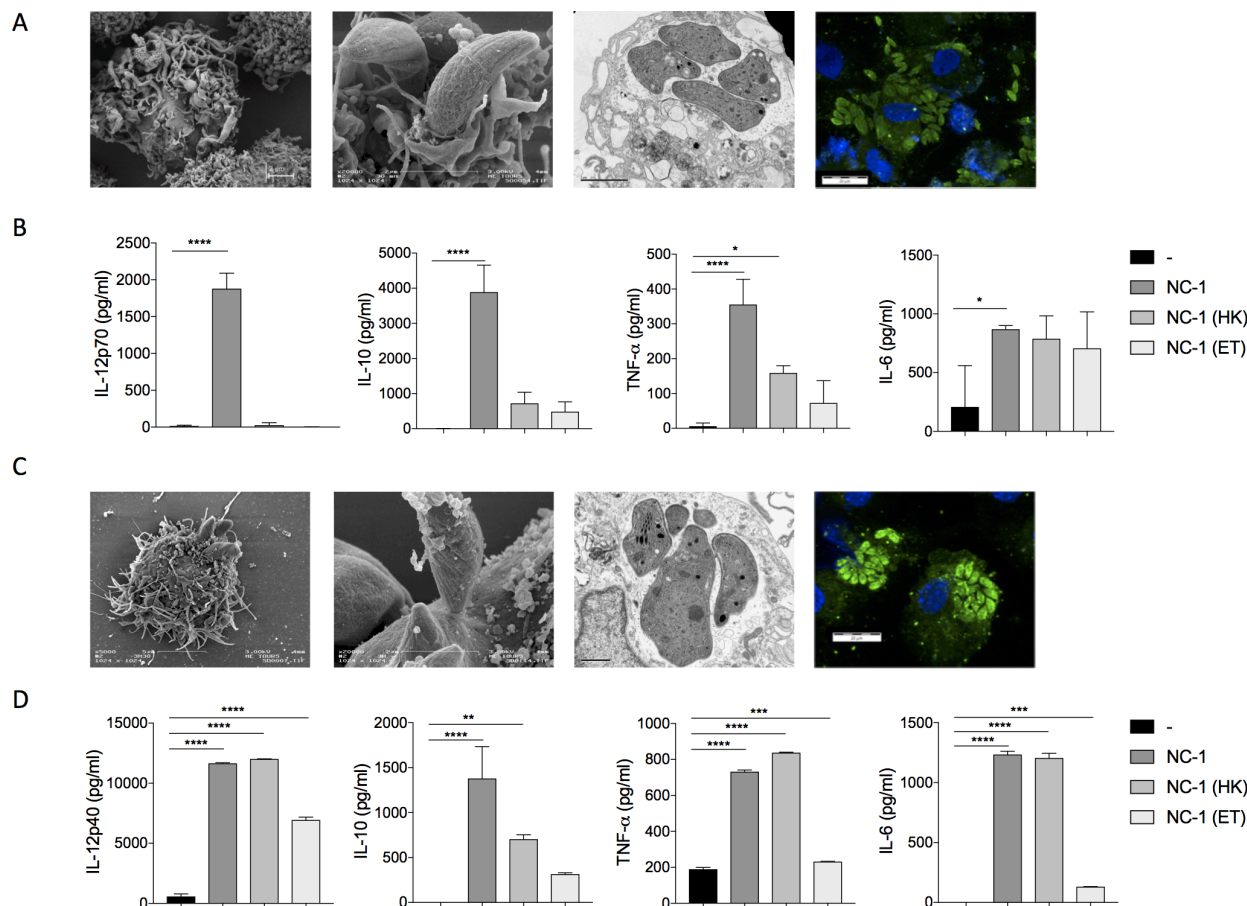

3

Figure 1 Immunostimulatory properties of *Neospora caninum* in vitro. At 4 hours and at 24 hours after infection with *N. caninum* tachyzoites (mutiplicity of infection (MOI) 3), mouse bone marrow dendritic cells (BMDCs) and human dendritic cells were fixated and prepared for electron microscopy or immunofluorescence assays were performed. First step of *N. caninum* infection (at 4 hours, 3 left panels) and cellular multiplication (at 24 hours, right panel) in human dendritic cells (A) and in mouse BMDCs (C) were thus visualized. For induction of cytokine expression, mouse BMDCs and human dendritic cells were cultured with or without *N. caninum* tachyzoites (MOI 1), alive or dead (as either whole dead organisms: heat-killed (HK) or as a total antigen extract from the protozoa: ET). After 24 hours of stimulation, supernatants were collected and the specified cytokines were assayed from the different lots of human dendritic cells (B) and of mouse BMDCs (D). *P<0.05; **p<0.01; ***p<0.001; ****p<0.0001.

observed *via* production of *N. caninum*-specific IgG and of IFN-γ in sera (online supplemental figure 2B-C). In parallel, survival of infected mice was recorded daily (online supplemental figure 2A). Except for the lowest dose of 2×10^3, the amount of specific IgG induced was essentially the same for all other doses. Concerning the cellular immune response, the highest doses (2×10^6 and 2×10^7) of protozoa were the most immunogenic as we observed a secretion of IFN-γ ($\cong 500$ pg/mL) in sera from the second day of infection. For lower doses, an IFN-γ production was observed only after a week. As the dose of 2×10^7 tachyzoites induced the death of all mice after 1 week, we decided to choose the dose of 2×10^6 parasites with a survival percentage of 60% for immunotherapy assays in mice.

Intratumorous delivery of *N. caninum* induces therapeutic antitumor effect

The antitumor effect of *N. caninum* was evaluated using the tumor-bearing mouse model wild type (WT) EG7 (PD-L1^{lo} EG7; OVA-expressing EL4 lymphoma). The EG7 cells were implanted in the right flank of C57BL/6 mice. To determine an optimal protocol and to assess whether the *intratumorous* injection of *N. caninum* could significantly inhibited tumor growth, 2×10^6 tachyzoites were injected 4 days after implantation with or without a second injection 3 days after (figure 2A).

We observed that intratumorous injection of protozoa significantly reduced tumor growth (figure 2B). Regardless of the protocol, tumors stopped growing 1 week after treatment and then rapidly regressed. Tumors from mice treated twice were undetectable in at least 85% of cases within 22–25 days, leaving a scar that disappears in the following days (figure 2C and J). If a drastic regression of tumors was observed for mice treated only once, very small tumors still persisted at the end of the protocol (<400 mm^3) suggesting the need for two injections. Moreover, no recurrence has occurred on treated mice >40 days after treatment (data not shown).
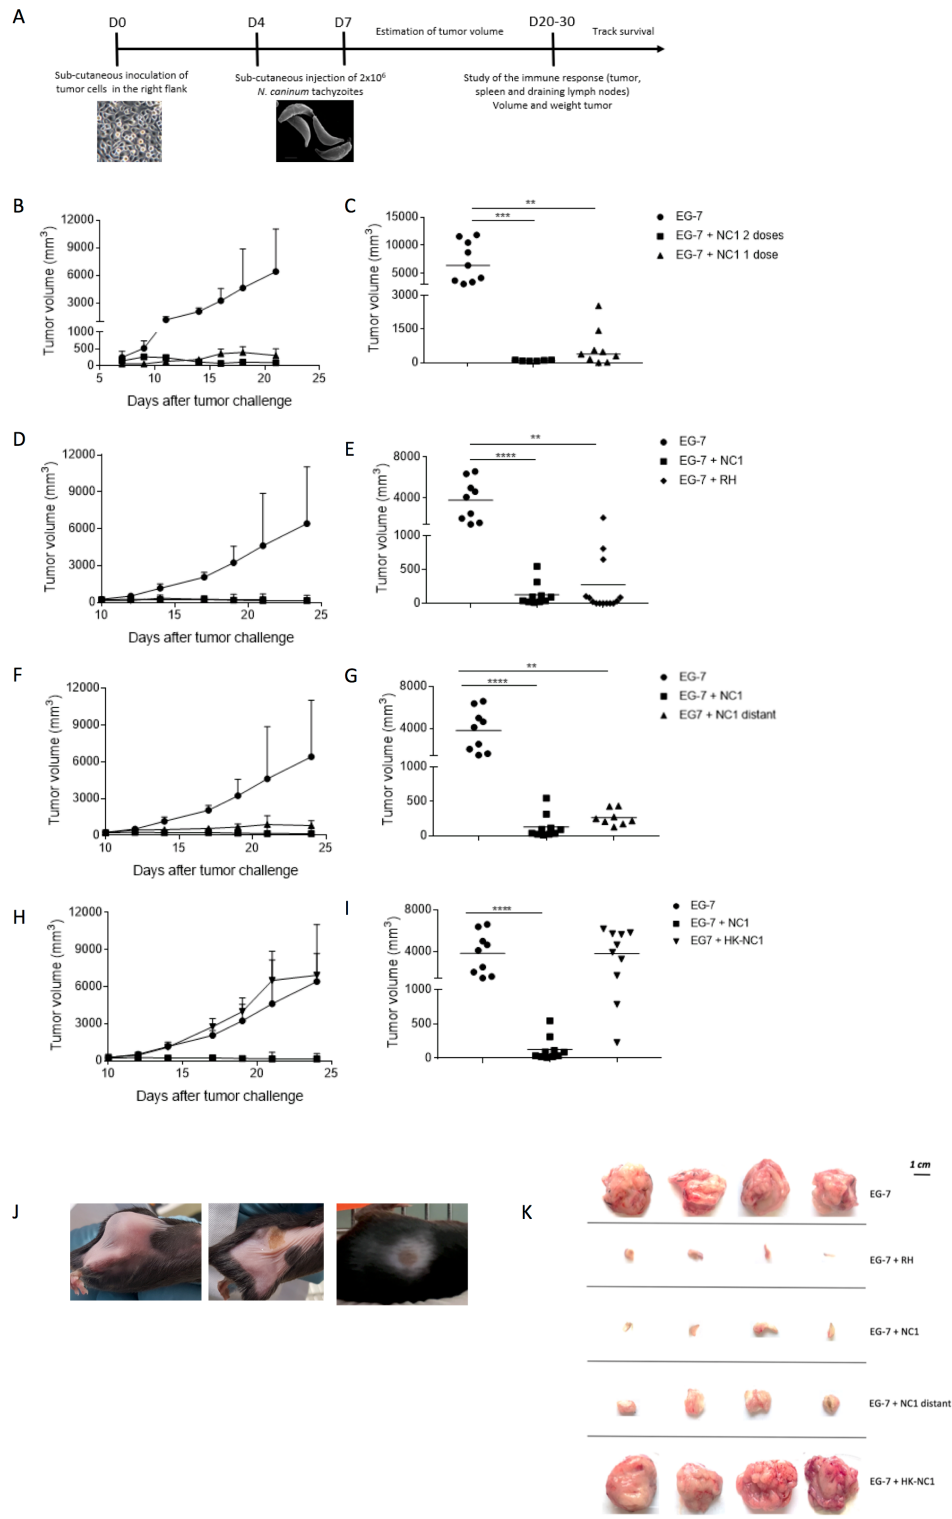

Figure 2 Tumor regression comparing *Neospora caninum* versus *Toxoplasma gondii* treatment in vivo. (A) Protocol of subcutaneous treatment with *N. caninum* (NC1) or *T. gondii* (RH) tachyzoites. EG7 cells (5×10^5) were inoculated subcutaneously in C57BL/6 mice and *N. caninum* tachyzoites (2×10^6) were injected intratumorally 4 or 4 and 7 days later: evolution of tumor development (B) and tumor volume at day 21 (C). *T. gondii* tachyzoites (500) were injected intratumorally on the same schedule: evolution of tumor development (D) and tumor volume was made at day 24 (E). Intratumorous and distant (flank opposed to the tumor) treatment with *N. caninum* at D4 and D7 postimplantation of EG7 cells have been compared: evolution of tumor development (F) and tumor volume was made at day 24 (G). Intratumorous treatment with alive or dead (heat-killed: HK-NC1) *N. caninum* at D4 and D7 postimplantation of EG7 cells have been compared: evolution of tumor development (H) and tumor volume was made at day 24 (I). (J) Fibrosis observed after *N. caninum* tachyzoites injection. (K) Macroscopic tumor size post-treatment with *T. gondii* tachyzoites (intratumorous) and *N. caninum* tachyzoites (intratumorous, distant or HK) at day 24. For each experiment, there are between 8 and 10 mice per group. **P<0.01; ***p<0.001; ****p<0.0001.

As *N. caninum* exhibited strong antitumor properties in a non-natural host, suggesting a potential efficacy in humans, we decided to compare its capacity with *T. gondii*, a naturally infectious parasite of rodents and humans, which had been shown to reverse tumor-associated immunosuppresion and to stimulate effective immune responses to eradicate established tumors.[18] After two injections of tachyzoites at the site of the tumor, both groups showed a strong inhibition of tumor development, and total clearance of tumors in some cases within 25 days (figure 2D, E and K). Thus, both *N. caninum* and *T. gondii* showed similar therapeutic properties against the EG7 tumor regardless of the mice being a natural or non-natural host of the agent used.

We then tested if *N. caninum* could still be effective if injected as a distant site from the tumor. As well as intratumorous delivery, remote inoculation succeeded to drastically decrease distant tumors. However, very small tumors persisted and total eradication was not obtained suggesting that *N. caninum* administration in the tumor microenvironment (TME) enhances its efficacy (figure 2F, G and K). Dead protozoa (heat-killed) failed to induce such tumor regressions; which indicated the need of live protozoa, for a direct or indirect oncolytic activity of *N. caninum* (figure 2H, 1 and K). To test the long-term effect of tumor treatment, mice in which a complete tumor regression had occurred were re-implanted with EG7 cells (25 days after the first implantation, on the opposite flank). While 100% of the mice injected for the first time with EG7 develop tumors, only 16,7% of the previously treated mice (2 out of 12 mice) harbored small tumors (50 vs 350 mm^3 in the control group), within 2 weeks. We observed that all remaining mice rejected the tumor rechallenge and remained tumor-free for 14 days. In naive mice, tumors can be observed as soon as 6 days postinjection of tumor cells and then reach an important volume of approximately 500 mm^3. Therefore, an absence of tumors in 14 days allow us to conclude that *Neospora* induce a protection against a rechallenge with EG7 tumor in those mice, showing that *N. caninum* therapy also induces a long-term antitumor immunity (online supplemental figure 3A,B).

Finally, we explored the effects of pre-existing anti-*Neospora* immunity on therapeutic efficacy. We infected mice with 2×10^6 tachyzoites of *N. caninum* and used the same treatment regimen 1 month after this first infection. We observed that primary infection did not affect the capacity of protozoa to induce a protective antitumor response as we obtained the same rate of tumor regression (online supplemental figure 3C).

These results demonstrate a durable efficacy of the antitumorous therapeutic treatments with *N. caninum*, preventing potential relapses without impact of a pre-existing *N. caninum* immunity, suggesting the possibility of repeated treatment without efficacy loss.

N. caninum does not persist in the organism following the induction of tumor regression

In order to decipher the antitumor potential of *N. caninum*, we investigated different possible mechanisms of protozoan-mediated tumor regression/destruction: 1) direct cytotoxic activity (oncolytic pathogens), 2) induction of antitumor immune response and 3) reprogramming the tumor microenvironment.

In vitro, transmission electron microscopy and immunofluorescence revealed that *N. caninum* tachyzoites were able to infect and multiply inside thymoma cells and lyze them (figure 3A). Four days after injection in mice, fluorescence microscopy revealed the presence of parasitophorous vacuoles (the replicative structure of Apicomplexa) in the tumor tissue, proof of the active replication of *N. caninum* in the TME (figure 3B, right panel). *N. caninum* was detected by qPCR in the tumor until 11 days post-treatment, but in quantity lower than the initial injected dose. However, beyond day 18 post-treatment, *N. caninum* was no longer detectable in the tumor or peripheral organs: spleen, brain and liver suggesting a natural clearance of the infectious agent by the mouse immune system (figure 3B). On the contrary, *T. gondii* was still detected in the tumor 25 days after the first injection, and in quantity far greater that the initial injected dose (200-fold), showing the high multiplication, and persistence abilities of *T. gondii* compared with *N. caninum*, despite similar antitumor efficacy. These results strengthen the interest, in efficacy and safety, of using a non-naturally infectious agent as a therapeutic, as *N. caninum* displays strong antitumor properties and is then naturally cleared from the organism.

N. caninum infection induces a measurable, systemic immune response and reprograms the tolerogenic tumor microenvironment

We evaluated systemic immune cell activation induced by *N. caninum* at blood and spleen levels. Four days after intratumorous inoculation of *N. caninum* tachyzoites, we observed an increase level of circulating IFN-γ, high levels of IFN-γ and IL-12 (online supplemental figure 6A) and low levels of IL-5, IL-10 and IL-17 in spleen with recruitment of DCs, macrophages and natural killer (NK) cells (online supplemental figure 6B). Of note, EG-7 cells being OVA expressing cells, splenocytes were stimulated in vitro with OVA for 72 hours, but no difference in expression of the 10 tested cytokines (including IFN-γ) was observed compared with unstimulated cells, therefore suggesting that the protection mechanisms observed are not OVA dependent (data not shown).

We then investigated in vitro, the ability of *N. caninum* to alter tolerogenic cells. BMDCs were cultured in presence of vitamin D$_3$ to induce a tolerogenic phenotype, characterized by a strong secretion of IL-10 and a very low secretion of IL-12 compared with control BMDCs (figure 3C). We confirmed that *N. caninum* tachyzoites were able to infect tolerogenic DCs (figure 3C) and, 18 hours after infection, to drive the tolerogenic DCs in a
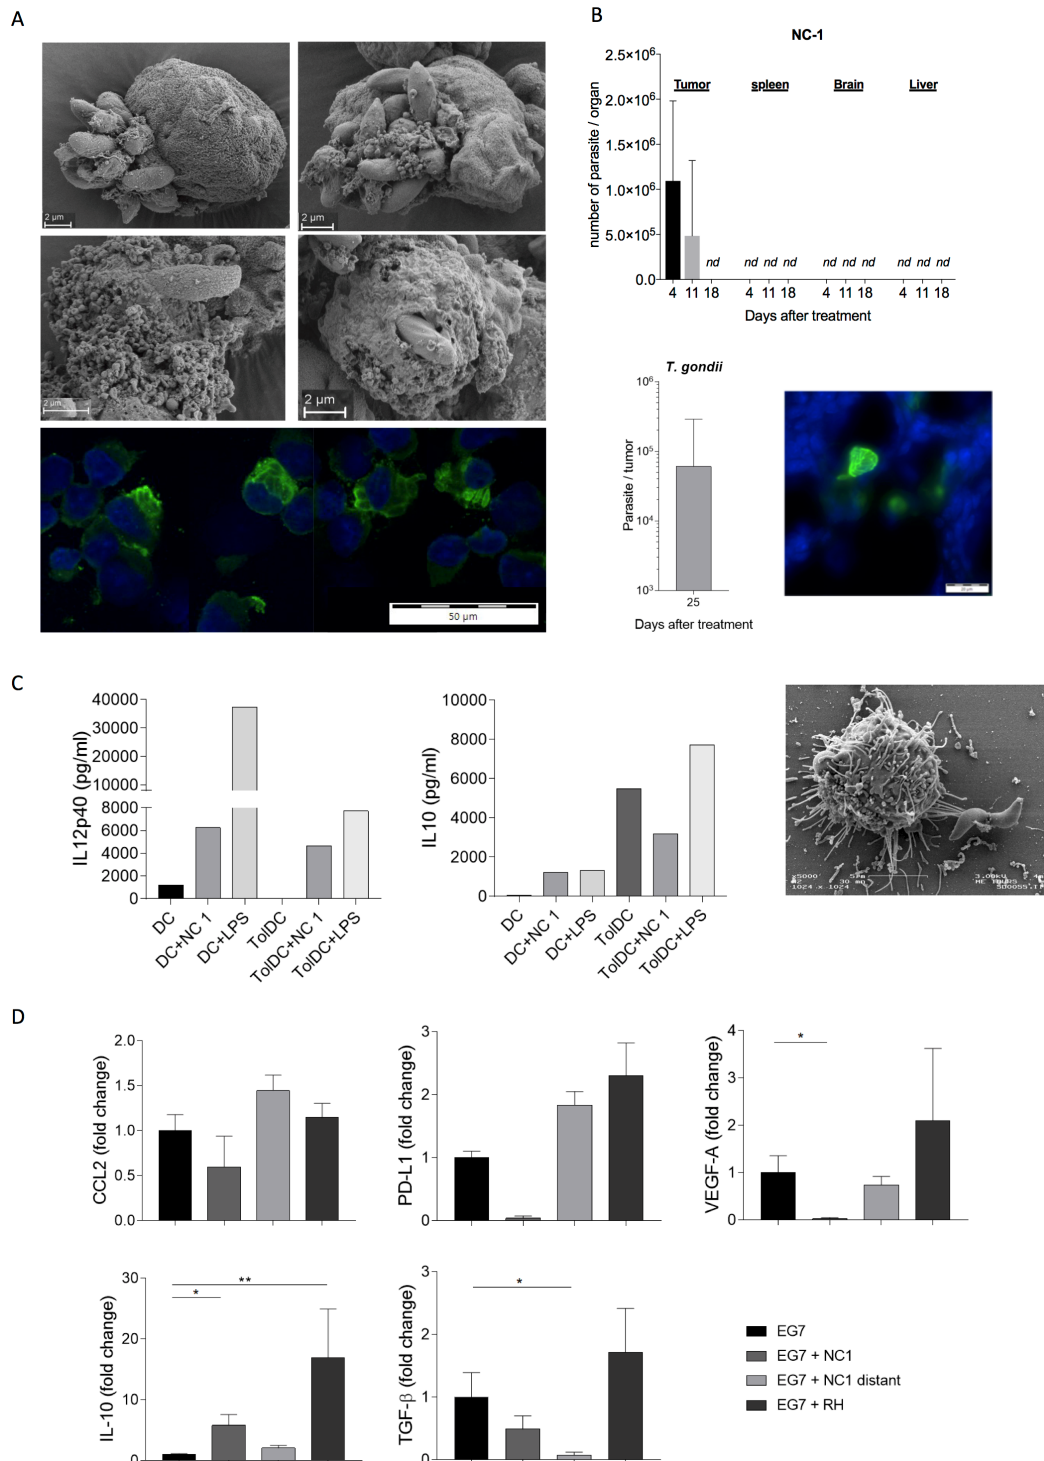

Figure 3 Non-persistence of *Neospora caninum* following tumor microenvironment reprogramming. In vitro, EG7 cells were cultured with *N. caninum* tachyzoites (MOI 3), then, 2 hours or 4 hours postinfection, cells were fixated for scanning electron microscopy; 24 hours postinfection, cells were fixated for immunofluorescence. The first phases of *N. caninum* infection (A, 4 top panels) and cellular multiplication (A, bottom panel) in mouse tumor EG7 cells are visualized. In vivo, EG7 cells (5×10^5) were inoculated subcutaneously into C57BL/6 mice and administered *N. caninum* (2×10^6, n=3) or *Toxoplasma gondii* (500, n=4) tachyzoites intratumorally 4 and 7 days later. Tumors and organs were collected at different times and the presence of the protozoan detected by quantitative PCR (qPCR) (B). Immunofluorescence assays were performed on tumor cryosections in order to visualize *N. caninum* tachyzoites (in green) 5 days after tumor inoculation (B). In vitro, mouse bone marrow dendritic cells (BMDCs) were cultured in presence of vitamin D_3 to induce a tolerogenic phenotype. Mice BMDCs (DCs) and tolerogenic BMDCs (TolDCs) were cultured with *N. caninum* tachyzoites (NC1, MOI 1). Eighteen hours postinfection, secretion of interleukin (IL)-10 and IL-12 by infected and uninfected cells were compared (C) and electron microscopy on infected tolerogenic BMDCs were performed (C). In vivo, 21 or 24 days after EG7 cells inoculation and *N. caninum* (NC1) or *T. gondii* (RH) treatment, tumors were collected, dissociated and assayed for various immunosuppressive molecules (D), n=10 mice per lot. *P<0.05; **p<0.01.

non-tolerogenic pattern, once again secreting high levels of IL-12 and low level of IL-10 as compared with control uninfected cells.

Analysis of common immunosuppressive factors, ex vivo, revealed that *N. caninum* treatment induced a reduction of factors associated with poor prognosis: VEGF-A, PD-L1, IL-10 and TGF-β profile within the EG-7 TME (figure 3D). The favorable capacity seemed specific to *N. caninum* in contrast to *T. gondii* that induced an increased pattern of poor prognostic factors (figure 3D).

Together, those results show that *N. caninum* is able to reprogram tolerogenic cells and reverse the in vivo immunosuppressive environment into an immune-competent antitumor environment.

N. caninum recruits immune cells in the tumor microenvironment to promote an effective T helper 1 immune responses

Generation of an efficient tumor-specific immune response is crucial to sustain tumor control. Cellular and molecular mechanisms underlying protective effects of *N. caninum* were also studied at tumor level and tumor infiltration was characterized by immune cell phenotyping and cytokine secretion. Hematein-phloxin-saffron stained tumors revealed that almost no necrosis was observed in untreated tumors (median necrotic area=3.1% of the tumor area) while large areas of necrotic tumor cells were observed in mice treated with live *N. caninum* (median necrotic area=35.8% in NC1-treated group) as shown in figure 4A,B. Necrotic areas within NC1-treated tumors were infiltrated with neutrophils with hypersegmented nucleus, a histological feature of 'activation' (N1) as compared with untreated tumors infiltrated with neutrophils of less segmented (ring-shaped) nucleus suggesting an ' immature' (N2) phenotype (figure 4C).

Histological observation and confocal mosaic reconstitution of large section of the tumor parenchyma of untreated mice showed a dense network of EG7 cells (CD3$^+$) without necrosis (figure 4A and D), with regularly scattered macrophages (CD68$^+$) and few neutrophils (Ly6G$^+$).

Following NC1 treatment, the parenchyma of the tumor showed a dismantled cellular structure (figure 4A and E) highly infiltrated with neutrophils and macrophages, with EG7 cells (CD3$^+$) harboring a necrotic phenotype (altered DAPI staining) and highly infiltrated with clusters of neutrophils (Ly6G$^+$) intermixed with macrophages (CD68$^+$) (figure 4E). Higher magnification of tumor sections from NC1-treated mice clearly suggests the close interaction of neutrophils and macrophages within those inflammatory clusters as indicated by the presence of merged area (yellow) of Ly6G and CD68 staining (figure 4F). Three-dimensional reconstitution of Z stacks from confocal images of the tumor parenchyma of NC1-treated mice confirms those interactions within areas of dense infiltrates (figure 4H) on the contrary of untreated mice (figure 4G). Finally, the staining of *N. caninum* tachyzoites within the tumor 5 days after the first

treatment (so before *Neospora* clearance) revealed that the tissue distribution of *Neospora* does not seem to follow a particular pattern as tachyzoites can be observed in all areas of the tumor as displayed on large section images (figure 4I).

Moreover, we can assume that *Neospora* can invade immune cells in vivo, as tachyzoites were colocalized with macrophages (figure 4I and J) within the TME.

We investigated by flow cytometry the immune cell infiltration in the TME. The total amount of myeloid cells was significantly higher in mice treated intratumorally with *N. caninum*. An 8-fold increase of neutrophils was observed in the tumor, associated with a 3.3-fold increase of macrophages (F4/80$^+$ cells) (figure 5A). The number of lymphoid cells also increased in the treated groups, with high infiltration of NK cells (4.4-fold), CD8$^+$ T cells (13-fold) and CD4$^+$ T cells (2.4) suggesting the development of innate and adaptive immune responses (figure 5A). A somewhat similar profile was observed with the *T. gondii* treatment. Still, *T. gondii* seems to induce preferentially a recruitment of macrophages and B cells in the tumor, while *N. caninum* treatment induces preferentially the recruitment of neutrophils and CD8$^+$ T cells.

A similar profile—to a lesser extent—was observed in tumors of mice with remote site treatment. Moreover, as expected, no variation in cell population was found in tumors of mice treated with heat-killed parasites (data not shown).

The increase of those cell populations was correlated with a strong increase of T helper (Th)1 profile cytokines in the TME. Indeed, *N. caninum* treatment induces a strong increase in the secretion of IL-12, IFN-γ, IL-2 and TNF-α in the TME (figure 5B). As expected, a similar profile was observed in the remotely treated group, but with a lower increase, correlating with the immune cell populations data.

As a matter of comparison, *T. gondii* strongly increased the secretion of a broad range of cytokines, and the effect on Th1 profile cytokines was similar to the one observed with *N. caninum*.

N. caninum antitumorous activity is dependent on macrophages, NK cells and CD8$^+$ T cells

In order to assess the respective involvement of immune cells in the *Neospora*-induced antitumor effect, we administered anti-CD4, anti-CD8, anti-NK1.1, anti-Ly6G monoclonal antibodies (mAbs) or chlodronate liposomes (macrophages depletion) from D1 after *Neospora* injection, to deplete the respective cell populations. While injection of anti-NK1.1, anti-CD8 mAbs and chlodronate liposomes completely abolished the antitumor activity of *Neospora*, anti-Ly6G and anti-CD4 mAb did not have any effect on the tumor regression (figure 6). These data show the critical role of NK cells, CD8$^+$ T cells and macrophages in the protection processes induced by *N. caninum* treatment.
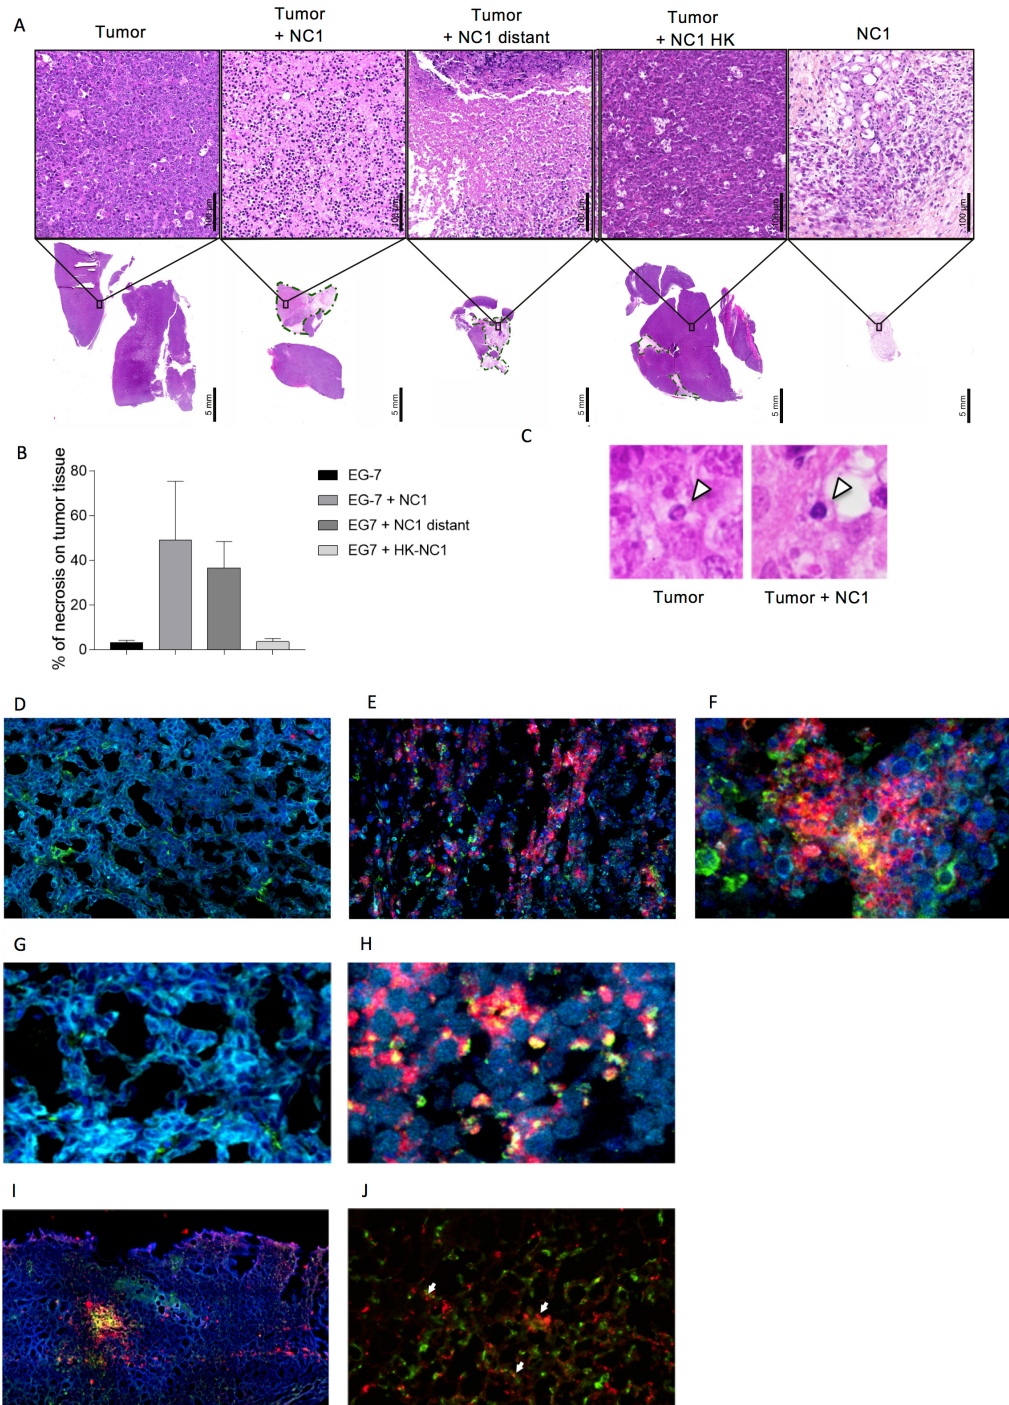

Figure 4 Tissue necrosis and cellular network structure of EG7 tumor following *Neospora caninum* treatment. Twenty-four days after EG7 cells inoculation and *N. caninum* (NC1) treatment, tumors were collected for histological analysis and immunofluorescence staining, respectively. Representative specimens from experimental and control groups are depicted (hematein-phloxin-saffron staining, bars=5 mm and 100 µm, respectively) (A). Percentage of necrotic areas, harboring pyknotic, dark nuclei, intermixed with an inflammatory infiltrate composed of neutrophils and macrophages within control and treated tumors were evaluated (B), between 3 and 5 mice per lot. Phenotypes of infiltrating neutrophils in control tumor: ring-shaped/banded nucleus/slightly segmented suggesting an immature phenotype or N2 neutrophil and in NC1-treated tumor: hypersegmented nucleus suggesting a mature phenotype or N1 neutrophil (C). Representative confocal images of EG7 tumor 8 µm cryosections: mosaic reconstitution of large sections from untreated (D) and NC1-treated mice (E) and higher magnification of tumor sections from NC1-treated mice (F). Tumors were labeled with anti-Ly-6G for neutrophils (red), anti-CD3 for EG7 thymoma cells (cyan), anti-CD68 for macrophages (green) and counterstained with DAPI (4',6-diamidino-2-phénylindole, for nuclei (blue). Representative three-dimensional reconstitutions of Z stack from untreated (G) and NC1 treated (H) were performed. Five days after the first *Neospora* injection, tumor were collected and stained for *Neospora* (red) and macrophages (CD68, green) and acquisition of large section were taken (I), larger magnification images were observed to visualize colocalization (J).
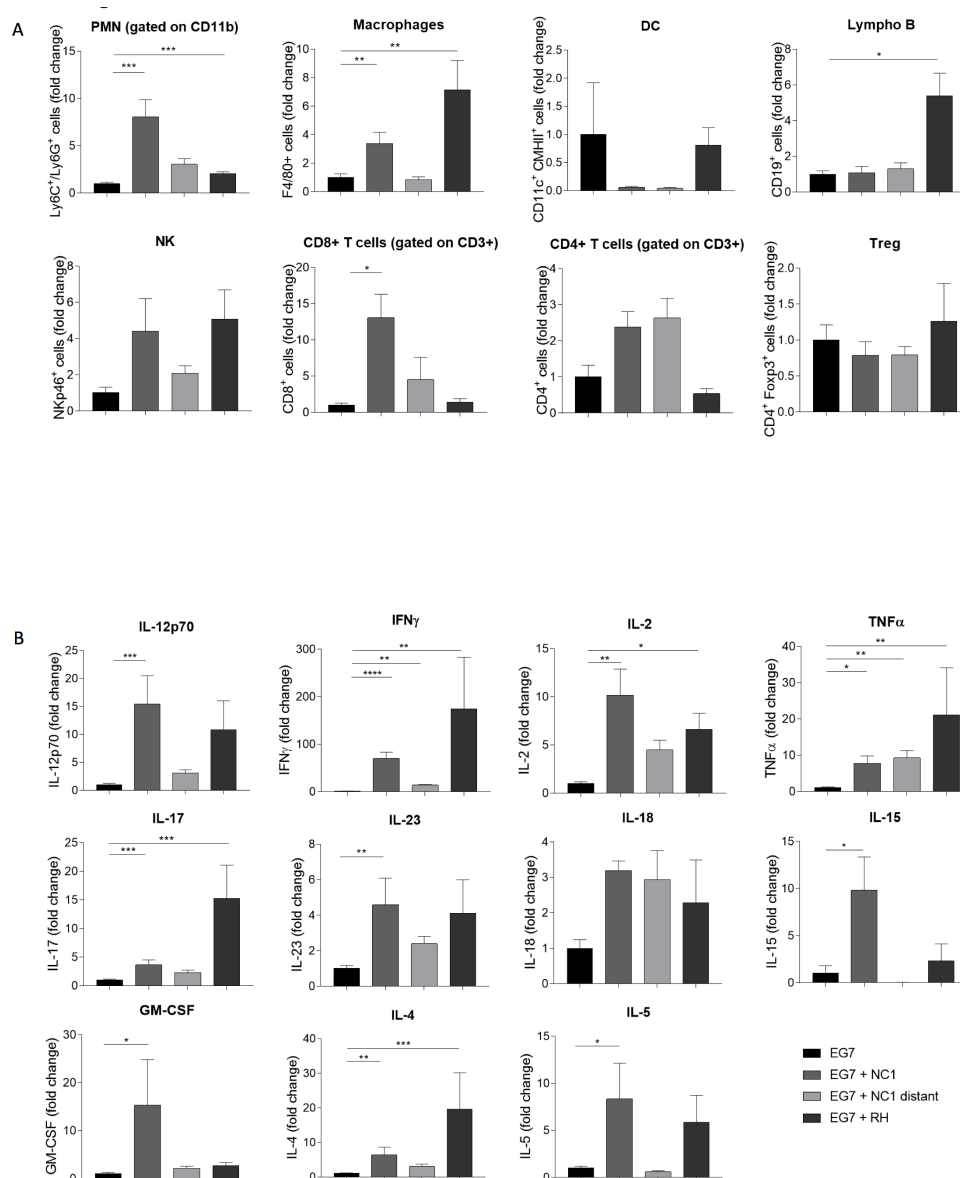

Figure 5 Induction of a T helper (Th)1 antitumor immune response after *Neospora caninum* treatment. EG7 cells (5×10^5) were inoculated subcutaneously in C57BL/6 mice and, 4 and 7 days later, *N. caninum* (NC1, 2×10^6) or *Toxoplasma gondii* (RH, 500) tachyzoites were injected intratumorally. Twenty-four days after EG7 cells inoculation, tumors were collected and dissociated. The cell suspension was centrifugated and cells were resuspended for staining and flow cytometry analysis, n=5 mice per lot (A). Cytokines production in tumor dissociation supernatant was evaluated by ELISA or multiplex analysis, n=10 mice per lot (B). *P<0.05; **p<0.01; ***p<0.001; ****p<0.0001.

N. caninum induces regression of human Merkel cell carcinoma

In order to assess the effect of *N. caninum* on human tumors, we used a model of NOD/SCID mice bearing human MCC. After treatment, tumors of around $600\,\mathrm{mm}^3$ regressed to a measured volume of $200\,\mathrm{mm}^3$ (figure 7A). MCC that developed into established tumors (about $1000\,\mathrm{mm}^3$ at day 43 postinoculation) were injected with *N. caninum* tachyzoites (figure 7A). The volume of established tumors also regressed by threefold, 10 days after treatment.

As expected due to their extremely immunocompromised status, the NOD/SCID mice ended up dying of the *N. caninum* infection. Hence, qPCR analysis

revealed an average of 2×10^8 tachyzoites per gram of tumor (figure 7B), showing that without the immune pressure, the protozoan has multiplied extensively within the tumor. Thus, the total and natural clearance of the parasite previously observed in WT mice is most probably related to their immune status, and not to a defect in the parasite ability to replicate in host cells (figure 3B).

The ability of the protozoan to infect and multiply in human tumor Merkel cells was confirmed in vitro by scanning electron microscopy and immunofluorescence (figure 7C). These data indicate the potential of *N. caninum* to infect and multiply in human tumor cells.
Figure 6 Impact of differential immune cell depletion on tumor regression following *Neospora caninum* treatment. EG7 cells (5×10^5) were inoculated subcutaneously in C57BL/6 mice and, 4 days later, *N. caninum* (2×10^6) tachyzoites were injected intratumorally. One day after *N. caninum* treatment and then every 2–3 days until sacrifice of the mice, anti-CD4, anti-CD8, anti-NK1.1, anti-Ly6G monoclonal antibodies (mAbs) or chlodronate liposomes (macrophage depletion) were injected intratumorally. Evolution of tumor development was followed every 2–3 days. n=6 mice (phosphate-buffered saline (PBS)) and 10 mice (other lots). Individual values are shown in online supplemental figure 4).

Engineered *N. caninum* secreting human IL-15 is able to enhance human immune cell activation

Improving the protective effects of *N. caninum* seems essential in order to obtain a total protection in advanced or refractory tumors. To this aim, we engineered a *N. caninum* strain able to secrete the human IL-15 (cross-reactive with mouse cells), associated with its sushi domain (alpha-subunit of the IL-15 receptor), increasing its stability, binding and biological abilities, to strongly induce the expansion of Th1-associated lymphocyte subsets and prevent their apoptosis in vivo.[27]

We first assessed that the engineered clones were able to secrete a biologically active form of the cytokine (figure 7D). We showed that supernatant of NC1-IL15hRec cultures was able to induce IFN-γ secretion by mouse splenocytes in vitro, 4 to 5 times more than supernatant from WT *Neospora* (figure 7E). The NC1-IL15hRec strain was thus able to secrete a functional IL-15 in its environment.

We then tested the effect of the NC1-IL15hRec strain on human cells. Human PBMCs were infected with NC1 and NC1-IL15hRec. After 24 hours, levels of IL-15 in the supernatant were only detectable for cells treated with NC1-IL15hRec (figure 7F). Then we observed that, as

the recombinant IL-15, the NC1-IL15hRec strain was able to induce proliferation of human NK cells as shown by the increase of Ki67 expression by human NK cells (figure 7G). Meanwhile, WT *N. caninum* displayed a much lower increase of proliferation by NK cells. Moreover, while recombinant IL-15 was only able to induce proliferation, but not IFN-γ secretion, by human PBMCs, NC1-IL15hRec induced a strong IFN-γ secretion by human PBMCs, much more than WT *N. caninum* (figure 7H). Finally, EG7 bearing mice were treated intratumorally with NC1 or NC1-IL15hRec tachyzoites. This experiment revealed, after two injections of tachyzoites at the site of the tumor, an added-value of the IL-15 secretion by *Neospora*, as the volume of treated tumors was significantly smaller in tumor treated with NC1-IL15hRec compared with NC1 treatment (figure 7I and J). The analysis of immune cells in the TME revealed that the improved protection was also correlated with an increase of NK cells, CD8T cells and CD4 T cells in the tumor microenvironment (online supplemental figure 4A). No added value was observed for the recruitment of DCs and macrophages. Of note, the level of expression of MHC-II on DCs or macrophages remained unchanged after *Neospora* treatment, regardless of the strain used, as shown in online supplemental figure
Figure 7 Evaluation of the oncolytic activity of *Neospora caninum* in human tumor. WaGa (10^7, associated with 10% Matrigel (10 mg/mL)) cells were inoculated subcutaneously into the right flank of non-obese diabetic/severe combined immunodeficiency (NOD/SCID) mice. Twenty-one days later (early tumor) or 43 days later (established tumor), *N. caninum* (2×10^6) tachyzoites were injected intratumorally: evolution of tumor development was followed every 2–3 days, n=4 mice per lot (A). When mice died, tumors were collected and the presence of the protozoan was detected by quantitative PCR (qPCR) (B). In vitro, WaGa cells were infected (MOI 1) with *N. caninum* tachyzoites. With scanning electron microscopy and immunofluorescence, the ability of the protozoan to infect (C, top panel) and multiply (C, bottom panel) in human tumor Merkel cells was confirmed, at 4 hours and 24 hours, respectively. Supernatants of cultures of the engineered NC1-IL15hRec strain and NC1 strain were assayed for interleukin (IL)-15 48 hours after infection (MOI 0, 2) (D). Mouse splenocytes were infected with NC1-IL15hRec (MOI 1) and interferon (IFN)-γ was assayed in the supernatant after 48 hours (E). Human peripheral blood mononuclear cells (PBMCs) were infected with NC1-IL15hRec or NC1 (MOI 1), and supernatants of cultures were assayed by ELISA 24 hours after infection (F, H). At the same point in time, cells were analyzed by flow cytometry (G). EG7 cells (5×10^5) were inoculated subcutaneously in C57BL/6 mice and *N. caninum* tachyzoites (2×10^6) of the NC1 or IL15hRec strain were injected intratumorally 4 or 4 and 7 days later: evolution of tumor development (I) and tumor volume at day 25 (J) are shown. n=5 for the EG7 group, n=10 for the treated groups.

5B). IL-15 was detected in the TME at D25, but was not detected in the blood of treated animals, suggesting a local secretion of IL-15 within the tumor, after *Neospora* treatment (online supplemental figure 5C).

Those data clearly demonstrated the added-value potential of an IL-15-armed strain of *N. caninum* that might enhance the already potent immunomodulatory properties of the WT protozoan.

DISCUSSION

This study reports the first use of *N. caninum* as an immunotherapeutic agent against cancer and demonstrates the strong efficacy of this protozoan in both destroying the cancer cells and unleashing potent immune responses, leading to tumor regression and eradication.

The use of live micro-organisms for their antitumorous properties goes back more than a century, when in the 1890s, William Coley treated patients with cancer by injecting live bacteria intratumorally and first succeeded in obtaining total regression of malignant tumors.[28] If this approach remained in the dark for decades, the recent rise of immunotherapy brought it back to light, essentially through oncolytic viruses. The first conceptual revolution of immunotherapy was the targeting or bypassing of the immunosuppressive signaling induced by the tumor and is currently supported by 11 immune checkpoint inhibitors and 2 CAR-T cell products, approved by the FDA.[29] Combination of both these strategies seems especially promising, thus allowing a specific destruction of cancer cells and the abolishment of tumorous immunosuppression.[30] The efficiency of cancer immunotherapy is based on these two aspects, and can be obtained with by a strong innate immune response initiated by a robust antigen presentation and priming process.

Oncolytic organisms trigger an antitumor immune response through direct lysis of the cancer cell and the subsequent release of tumor-associated antigens, damage-associated molecular patterns and pathogen-associated molecular patterns in the TME, altering the immunosuppressive environment of the tumor allowing activation of antigen presenting cells and alteration of the immunosuppressive environment of the tumor. Such effects induce tumor immune infiltration, potentially turning 'cold' tumors into 'hot'. In that matter, immunotherapy using the live microorganism *N. caninum* assesses all of these aspects. We first demonstrated in this study that *N. caninum* was able to induce strong activation of innate immune cells, correlated with an important secretion of IL-12 and TNF-α (figure 1 and online supplemental figure 1). In vivo, we demonstrated that *N. caninum* was able to thoroughly disrupt the tumor (figure 4), decreasing immunosuppressive factors (figure 3) and triggering immune cell infiltration. This tumor disruption was correlated to an increase in Th1 profile cytokine production in the TME (figure 5), thus leading to necrosis (figure 4), regression and/or eradication of a solid state tumor (figure 2).

The use of microorganisms meets strong interest but beset with challenges. Viral-based therapy is hampered by inefficient targeting, TME blocking and rapid clearance, while bacterial therapy suffers from toxicity.[31] In contrast, an innovative immunotherapeutic cancer treatment based on the tachyzoite stage of *Neospora*, presents advantages. *Neospora* belongs to the phylum Apicomplexa, a group of eukaryotic organisms that bear an apical complex which allows them to penetrate a wide variety of cell membranes. This may explain how the agents can penetrate tumors and cancer cells despite impediments and lack of specific host cell receptors.

In terms of pay load capacity, the production of tachyzoites is no more limited than a virus bioproduction. Tachyzoites are very stable, can be easily produced by culture on mammalian cells and injected multiple times. Unlike viruses, *N. caninum* does not present a mutagenic risk and it does not integrate into the genome of the host cell.

Like oncolytic viruses or bacteria, *N. caninum* is a powerful stimulant of the innate immune system, a prerequisite to effective priming of adaptive immune responses against both foreign antigens and tumor-associated ones. After treatment with *N. caninum*, we indeed observed an increase of specific antibodies for either *N. caninum* antigen or EG-7 antigen (OVA) in the TME (data not shown). The protection mechanisms that we described were also reported with other strategies: Vaccinia virus treatment in a colorectal tumor model was followed by massive tumor necrosis correlated with the influx of neutrophils impairing the tumor vascularity.[32] As observed with *N. caninum* in our model, NK cell depletion and CD8 depletion also impaired the efficacy of HSV therapy in melanoma[33] or adenovirus therapy in rectal tumors,[34] respectively, highlighting the crucial role of both these cell populations in the tumor elimination, in an immunotherapy context. It appears that *N. caninum* induced similar immune responses as other oncolytic microorganisms and displayed unique properties. Its ability to efficiently invade many cell types thanks to its specialized organelles, allowed *N. caninum* to overcome many barriers that can be met by others agents. *N. caninum* is hence able to easily and actively invade tumor cells, regardless of the expression of a specific receptor at its surface. This active motility and invasive capacity of the tachyzoites could overcome the physical barrier formed endothelial cells met in solid tumors, representing a big challenge for delivery of oncolytic viruses.[35] However, withal, we could suppose that *N. caninum* preferentially infects monocytes over other leukocytes, as described for *T. gondii*,[36] hence favoring stimulation of innate immune cells within the TME. We demonstrated that *N. caninum* was able to invade immunosuppressive innate immune cells that shifted back to an immuno-active state (figure 3), thus countering the defensive immunosuppression established within the TME. Such countermeasure to impairment of immune defenses, concomitant with immune infiltration of the tumor, leads to strong production of Th1 profile cytokines in the TME (figure 5); all of those factors being crucial for the total eradication of a solid state tumor. Another hypothetical protection mechanism is infection and then modification of tumor cells, which promotes their recognition by the immune system, leading to the activation of an adaptive immune response specific for *N. caninum*, and for tumor antigens, as it was observed with oncolytic viruses.[37] Future studies will be necessary to precisely investigate which cells are infected and what interactions occur between *Neospora* and the cells of the TME. Bioluminescent or fluorescent

strains of *Neospora* will be a necessary tool to precisely answer those questions.

One issue raised about microbial-based cancer therapy pertains to potential toxicity. *N. caninum* has characteristics that make it stand out in that matter as well. First, *N. caninum* has never been described as pathogenic in humans, making it an interesting candidate compared with other viruses, bacteria or protozoan that have been explored in cancer therapy. Our data also showed that after initiating strong immunological responses, *N. caninum* was naturally cleared from the tumor and the entire organism (figure 3). Moreover, acquired immunity against *N. caninum* did not impair the efficacy of future treatment (online supplemental figure 3), suggesting the possibility of repeating injections of *N. caninum* tachyzoites through time, without a loss of efficacy against the tumor. Altogether, those data suggest that *N. caninum* is a novel, safe and very promising agent for the treatment of solid-sate tumors. The tumor regression induced by a distant administration of *Neospora* also suggests that a protective effect could be observed in distant diseases or metastasis, if *Neospora* is administered by a systemic route. This approach is currently under investigation in the laboratory.

However, treatment of advanced and/or refractory tumors might require enhanced antitumor responses and functions. This could be obtained by combinatory strategies or genetic engineering of the oncolytic agent(s). Accordingly, several armed oncolytic virus or bacteria have been developed, notably viruses encoding type I[38 39] or type II[40] IFNs, to enhance their antitumorous efficacy. *Neospora*, as higher order eukaryotes, have a much larger genomic capacity than viruses or bacteria and can be relatively easy to engineer to carry one or more transgenic payloads. This translates as an ability to enable other molecules in a recombinant derivative and traffic them to tumor site(s) and into cancer cells. Arming of an oncolytic agent with the expression of a fusion protein of IL-15 and IL-15Ralpha had been explored and showed promising results with an engineered vaccinia virus in both colon and ovarian cancer model,[41] where expansion of NK cells and CD8 T cells was observed. In our study, we established that the NC1-IL15hRec strain was able to induce both cell proliferation and IFN-γ secretion by human PBMCs in vitro, thus reinforcing the immunostimulatory properties of *N. caninum.*

Altogether, our data suggest that through innate immune cell stimulation and, potentially, tumor-associated antigen release, *N. caninum* induces a specific adaptive immune response dependent on NK cells and CD8 T cells recruitment in the TME. Targeting these cells to enhance the antitumor responses through armed *N. caninum* might be the key to obtain total regression of tumors. Further studies will be necessary to develop an arsenal of different therapeutic *N. caninum* and assess their different mechanisms of action.

In summary, our study has revealed that the protozoan *N. caninum* can elicit potent antitumor immunity in vivo, in murine models of mouse and human tumors, and that modifying *N. caninum* to secrete the IL-15-IL15Ra complex in the microenvironment strongly augments its immunological properties. These data also highlight the potential of *N. caninum* engineered strains, to either secrete antitumor effectors, or express protein at its surface, extending the possible clinical applications of *N. caninum* to a wide range of cancer therapies.

Bone marrow cell isolation and human DCs

Bone marrow cells were collected from femur and tibia of C57 BL/6 mice as described previously [41].

Cells were plated at 4.10^6 cells/mL in low Petri dishes and cultured at 37°C, 5% CO2 in 10mL RPMI-1640 medium containing 10%FCS, 10mM HEPES, 1mM pyruvate, 2mM l-glutamine, 100U/mL penicillin, streptomycin (all from PAN BioTech), 1% non-essential amino acids (GIBCO), and 50 µM 2β-mercaptoethanol. For BMDCs and BMMs differentiation, 5ng/mL of GMCSF (J558L cell supernatant) and 20ng/mL of M-CSF (L929 cell supernatant) were added respectively. For tolerogenic DCs, 1,25 dihydroxyvitamin D3 1,25(OH)2D3 (Sigma) was added every 2 days at 10^{-8}M. Neutrophils were purified using the Neutrophils isolation Kit (Miltenyi biotech).

For humanDCs, Cytapheresis products were obtained from Centre Atlantic Transfusion Department (EFS-CA). An enriched DCs fraction was obtained by gradient centrifugation with Percol® (Healthcare) and cells were differentiated for 6 days in RPMI 1640 (Dutscher) medium supplemented with 10% FCS (Dutsher), 66ng/mL GM-CSF(Miltenyi Biotec) and 25ng/mL IL-4 (Miltenyi Biotec). At day 6, cells were collected and used for *in vitro* stimulation.

Immunofluorescence assays

Freshly collected tumors were incubated overnight at 4°C in 4% paraformaldehyde, 10% sucrose and then immersed in 30% sucrose for 4 h. Tumor tissue was snap frozen in OCT compound. Eight µm-thick cryosections were incubated 10 min in PBS 0.1% Triton X100 and blocked for 30 min with Fc-blocking antibody 2.4 G2 (BD Biosciences), washed in PBS 0.1% Tween 20 with 1% BSA and incubated overnight at 4°C with PE-conjugated anti-Ly-6G (clone1A8), (eBioscience), Alexa-488-conjugated anti-CD68 (clone FA-11, eBioscience) and APC-conjugated anti-CD3ε (clone 145-2C11, eBioscience). For *in vitro* infections, cells were fixed, with 4% paraformaldehyde for 30 min at room temperature, washed in PBS and permeabilized in PBS supplemented with 0,2% Triton X-100 for 20 min at room temperature. Tachyzoites were then labeled with primary (infection serum) and secondary antibodies (Alexa 488 Goat anti-rabbit IgG, Thermo Fisher Scientific). For non-adherent cells, cytospin were performed (1000rpm, 5min) prior to immunofluorescence staining. Images were captured with a confocal Leica TCS SP8 microscope using Leica LAS AF software, or Olympus IX73 microscope using CellSens Dimension software.

qPCR detection

N. caninum qPCR was performed on 250ng of genomic DNA in a total volume of 20µl containing 10µL of GoTaq® Probe qPCR Master Mix (Promega), 0.5µM of two primers (5'-TCCAATCCTGTAACGTGTTGCT-3'; 5'-CACAAACAAAAAGGAGCCTTGCT-3', Eurofins Genomics) specific for the *nc5* gene of *N. caninum*, and 180nM of the probe 5'-CTGCGCCCAACAAC-3' modified with 5'-FAM and 3'-TAMRA as reporter and quencher, respectively [42].

Electron microscopy

For scanning and transmission electron microscopy, cells were cultured in 24-well plates and were collected at various time points following the addition of *N. caninum* (MOI 5). Adherent cells were trypsinized (Pan Biotech), washed in PBS and fixed in 0.1M phosphate buffer (pH 7.2) containing 4% paraformaldehyde and 1% glutaraldehyde. Next, cells were prepared as previously described [43].

Pathologic examination

Hematein phloxin saffran stained slides were scanned by using NanoZoomer (Hamamatsu, Hamamatsu City, Japan). Based on morphology analysis, total and necrotic tumor areas were delineated by a pathologist on the digitalized slides and then analyzed using ImageJ software. Results are expressed in percentage of necrosis in tumor tissue.

Construction of the NC1-IL15hRec

Plasmid construction: The plasmid pUC8 CAT/GFP was used to construct the recombinants NC1-IL15hRec. pUC8 CAT/GFP-IL-15hRec is a pUC8 plasmid in which the sequence encoding the complex IL-15/IL-15Rα sushi (IL-15hRec) including the N-terminal signal sequence and the prodomain motif of MIC5 is cloned in the expression cassette between PmeI and NotI sites. pUC8 contains two expression cassettes. One was designed to express a CAT-GFP fusion protein to allow drug selection of stably transfected parasites, the second was designed to express proteins of interest. The expression of CAT-GFP is driven by the promoter of the *T. gondii* α-tubulin gene (αTUB5) and the 3'untranslated region (3'UTR) of the *T. gondii* SAG1 gene. The expression of the protein of interest is driven by the promoter of the *T. gondii* α-tubulin gene in which a five-repeat element was inserted upstream of the transcriptional start site (leading to promoter αTUB8 [27]).

Engineering of human recombinant cytokine IL-15 (IL-15hRec): Il-15hRec results from the association of the human sushi domain of the human IL-15 receptor subunit alpha precursor (GenBank: U31628.1) with the human

mature protein IL-15 (GenBank: U14407.1) via a peptide linker as described [44]. All these sequences were also optimized for protozoan organism (https://eu.idtdna.com/CodonOpt). IL-15hRec was synthesized as preproprotein with an N-terminal signal peptide and a separate, cleavable prodomain motif of MIC5. It was putchased from GenScript.

Production of human recombinant cytokine IL-15 (IL-15hRec) by N. caninum: Transfections were performed with 10^7 *N. caninum* tachyzoïtes in 650μL of cytomix [45] containing 3mM ATP and 3mM glutathione and 50μg of purified plasmid DNA (the plasmids were purified using the Qiagen kit®) linearized with PciI. Electroporations were performed in disposable cuvettes with an electroporator Biorad (2000 V, 50 ohms, 25 mF). After electroporation, the parasites are kept in the hood for 15 min at room temperature and then transferred to a fresh culture of fibroblast monolayers. After 24h *N. caninum* are respectively subjected to 80μM of chloramphenicol selection. After 15 days of selection, the parasites are cloned by limiting dilution in the wells of a 96-well plate of HFF cells in the presence of selection agent and the clones are amplified.
